  - Chapters 05 and 06

# Actual network growth is complex

A snapshot of the Autodesk organizational hierarchy was taken each day between May 2007 and June 2011, a span of 1498 days.

Each day the entire hierarchy of the company is constructed as a tree with each employee represented by a circle, and a line connecting each employee with his or her manager.

Larger circles represent managers with more employees working under them. The tree is then laid out using a force-directed layout algorithm.

From day to day, there are three types of changes that are possible:

- Employees join the company
- Employees leave the company
- Employees change managers

“Good get richer”  
(incl. Bianconi-Barabási model)

# “Good get richer” simulation (number is attractiveness)

# “Good get richer”

- A “good get richer” model is one where
  - Each node has an “attractiveness” (called “fitness”)
  - Preferential attachment is guided by this fitness  $\eta_i$
- The probability of connecting to node  $i$  is:

$$\Pi_i = \frac{\eta_i k_i}{\sum_j \eta_j k_j}$$

# Degree dynamics

$$\frac{d}{dt}k_i = m \frac{\eta_i k_i}{\sum_j \eta_j k_j}$$

$$k_i(t; t_i, \eta_i) = m \left( \frac{t}{t_i} \right)^{\beta(\eta_i)}$$

- With the dynamic exponent  $\beta(\eta_i) \propto \eta_i$
- Remember that in linear preferential attachment  $\beta = 1/2$  (for all nodes)

In preferential attachment (BA)  
a “younger” node cannot overtake  
an “older” node

Linear plot

Log-log plot

# In good-get-richer (Bianconi-Barabási) this depends on node fitness

Linear plot

Log-log plot

# Degree distribution

$$p_k \propto \int \frac{\rho(\eta)}{\eta} \left( \frac{m}{k} \right)^{\frac{c}{\eta} + 1} d\eta \quad \eta \sim \rho(\eta)$$

- When  $\eta$  is constant this reduces to BA
- When  $\eta$  is uniformly distributed in  $[0, 1]$  this also yields a power law but instead of  $\gamma = 3$  we get  $\gamma \approx 2.3$

Which distribution is more heterogeneous?

# Sub-linear and super-linear preferential attachment

# Sub-linear and super-linear preferential attachment

- The model we have studied so far has **linear preferential attachment** because  $\frac{d}{dt}k_i \propto k_i$
- We could imagine cases where  $\frac{d}{dt}k_i \propto k_i^\alpha$  for  $\alpha > 1$  or  $\alpha < 1$

What do you think should happen in each case?

# Measuring preferential attachment

- We should try to measure  $\Pi(k_i) \approx \frac{\Delta k_i}{\Delta t}$
- This can be too noisy
  - Why?
- Instead we will measure  $\pi(k) = \sum_{k_i=0}^k \Pi(k_i)$
- If  $\Pi(k_i)$  is constant  $\pi(k) \propto k$
- If  $\Pi(k_i) \propto k$  then  $\pi(k) \propto k^2$

# Preferential attachment in a citation network

- We observe it follows preferential attachment (with  $\alpha = 1$ ) in this case

# The degree of the largest hub $k_{\max}$

SUBLINEAR

LINEAR

SUPERLINEAR

# Aging effects

# Sick Boy's unified theory of life from *Trainspotting* (1996)

In Spanish: [https://www.youtube.com/watch?v=cN\\_WbiuqyQU](https://www.youtube.com/watch?v=cN_WbiuqyQU)

English (bad audio) subs in Spanish: <https://www.youtube.com/watch?v=4xTWD9GNRFA>

# Aging effects

- Models without fitness but with a negative effect of age

$$\Pi(k_i, t - t_i) \approx k_i(t - t_i)^{-v}$$

- Older nodes accumulate links more slowly
- Parameter  $v$  is the decay factor

Qualitatively, what would you expect if:

$$v < 0 \quad v = 0 \quad v \approx 1 \quad v \gg 1$$

# Aging effects

- $v < 0$  favors older nodes
- $v = 0$  is simply preferential attachment
- $v \gg 1$  means only youngest are linked

$v = -10$

$v = 0$

$v = 1$

$v = 10$

# Power-law exponent in models with aging ( $N=10K$ , $m=1$ )

More  
heterogeneous

More  
homogeneous

Advanced materials  
(not included in the exam):

(1) No preference (2) No growth

# Remember preferential attachment

- Start with  $m_0$  nodes
- At every time step
  - Add one new node  $u$
  - Repeat  $m$  times
    - Pick a node  $v$  with probability  $\Pi(k_v) = \frac{k_v}{\sum_j k_j}$
    - Connect  $u$  to  $v$

# Two simple variants

- No preference
  - Nodes receiving inlinks are picked uniformly at random
- No growth
  - The network starts with  $N$  nodes
  - No new nodes are created

# No preference model

- Write the process on paper
- Write  $\Pi(k_i)$
- Noting that  $\frac{d}{dt}k_i = m\Pi(k_i)$  obtain  $k_i(t)$

$$\int \frac{a}{b+x} = a \log(b+x) + C$$

# No preference model (cont.)

- Compute  $Pr(k_i(t) > k)$  assuming large  $t, t_i$
- Use it to compute
$$Pr(k_i(t) \leq k) = 1 - Pr(k_i(t) > k)$$
- Derive to obtain  $p_k = Pr(k_i(t) = k)$

# Consequences of the “no preference” model

$m=1$ ,  $m=3$ ,  $m=5$ ,  $m=7$

- Degree decays exponentially  $p_k \propto e^{-k/m}$
- No power-law
- No large hubs

# No growth model

- Write the process on paper
- You will need to impose  $k_i(t_i) \neq 0$  why?
- Write  $\Pi(k_i)$
- Noting that  $\frac{d}{dt}k_i = \Pi(k_i)$  obtain  $k_i(t)$

# Consequences of the “no growth” model

$N=100K$

$t=N$ ,  $t=5N$ ,  $t=40N$

- Degree grows linearly  $k_i(t) \propto t$
- Degree distribution is not stationary
